REGRESSION MODEL WITH TWO EXPLANATORY VARIABLES

 $\mathbf{Y} = \boldsymbol{\beta}_0 + \boldsymbol{\beta}_1 \boldsymbol{X}_1 + \boldsymbol{\beta}_2 \boldsymbol{X}_2 + \mathbf{e}_i$

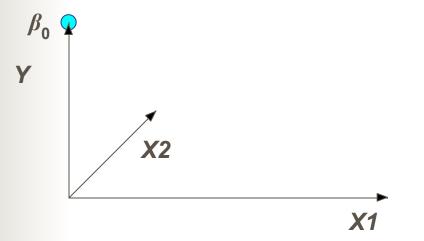

This sequence provides a geometrical interpretation of a multiple regression model with two explanatory variables.

- Y weekly salary (\$)
- X1 length of employment (in months)
- X2 age (in years)

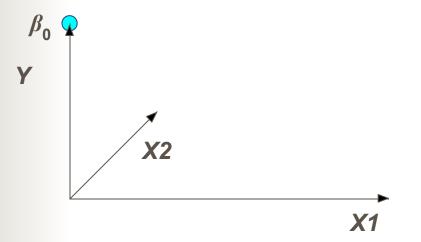

Specifically, we will look at weekly salary function model where weekly salary, Y, depend on length of employment X1, and age, X2.

- $\mathbf{Y} = \boldsymbol{\beta}_0 + \boldsymbol{\beta}_1 \boldsymbol{X}_1 + \boldsymbol{\beta}_2 \boldsymbol{X}_2 + \mathbf{e}_i$
 - Y weekly salary (\$)
- X1 length of employment (in months)
- X2 age (in years)

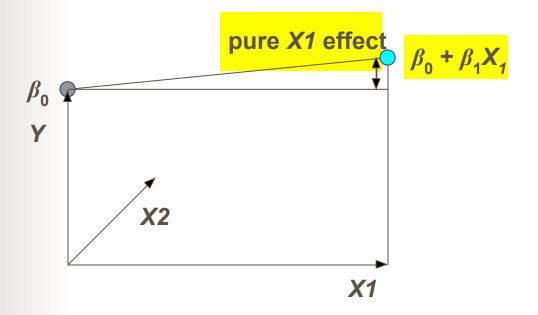

The model has three dimensions, one each for *Y*, *X1*, and X2. The starting point for investigating the determination of *Y* is the intercept, β_0 .

- $\mathbf{Y} = \boldsymbol{\beta}_0 + \boldsymbol{\beta}_1 \boldsymbol{X}_1 + \boldsymbol{\beta}_2 \boldsymbol{X}_2 + \mathbf{e}_i$
 - Y weekly salary (\$)
- X1 length of employment (in months)
- X2 age (in years)

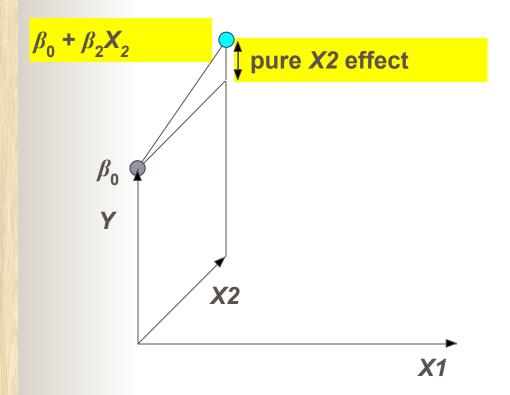

Literally the intercept gives weekly salary for those respondents who have no age (??) and no length of employment (??). Hence a literal interpretation of β_0 would be unwise.

- $\mathbf{Y} = \boldsymbol{\beta}_0 + \boldsymbol{\beta}_1 \boldsymbol{X}_1 + \boldsymbol{\beta}_2 \boldsymbol{X}_2 + \mathbf{e}_i$
 - Y weekly salary (\$)
- X1 length of employment (in months)
- X2 age (in years)

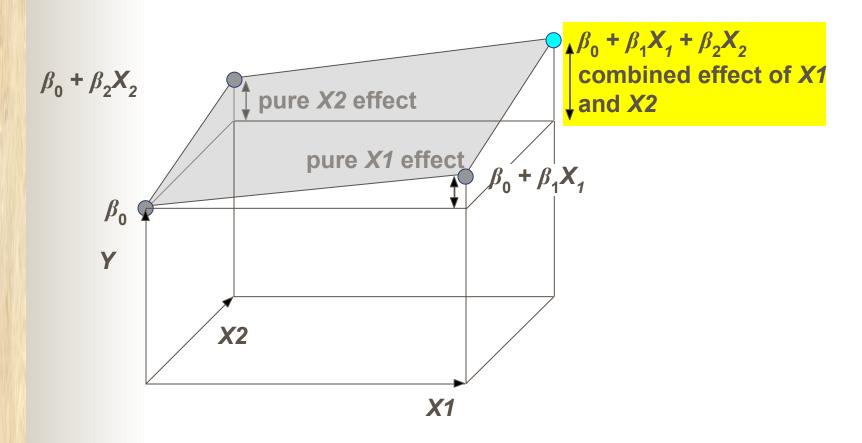

The next term on the right side of the equation gives the effect of X1. A one month of employment increase in X1 causes weekly salary to increase by β_1 dollars, holding X2 constant.

 $\mathbf{Y} = \boldsymbol{\beta}_0 + \boldsymbol{\beta}_1 \boldsymbol{X}_1 + \boldsymbol{\beta}_2 \boldsymbol{X}_2 + \mathbf{e}_i$

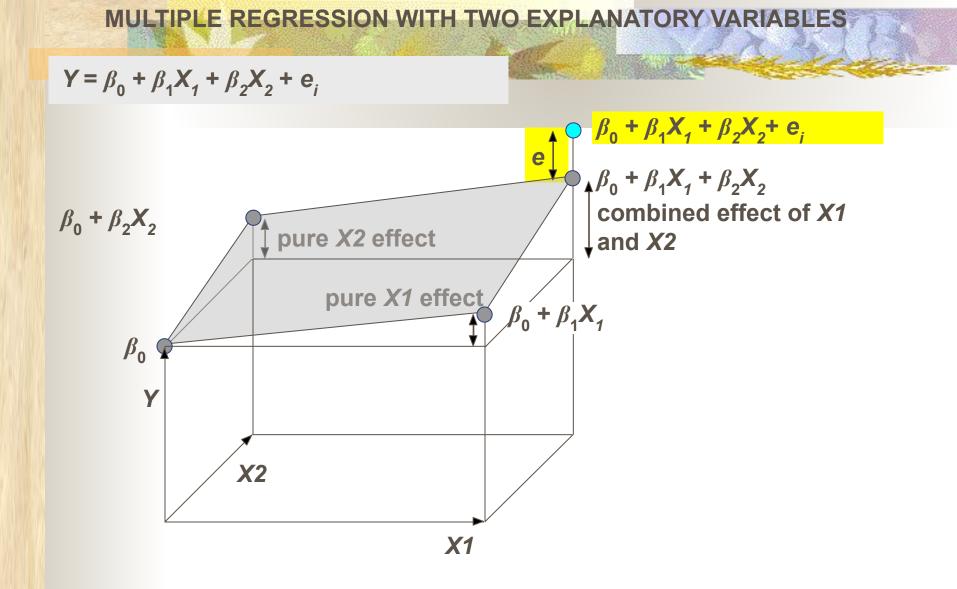

Similarly, the third term gives the effect of variations in X2. A one year of age increase in X2 causes weekly salary to increase by β_2 dollars, holding X1 constant.

 $\mathbf{Y} = \boldsymbol{\beta}_0 + \boldsymbol{\beta}_1 \boldsymbol{X}_1 + \boldsymbol{\beta}_2 \boldsymbol{X}_2 + \mathbf{e}_i$

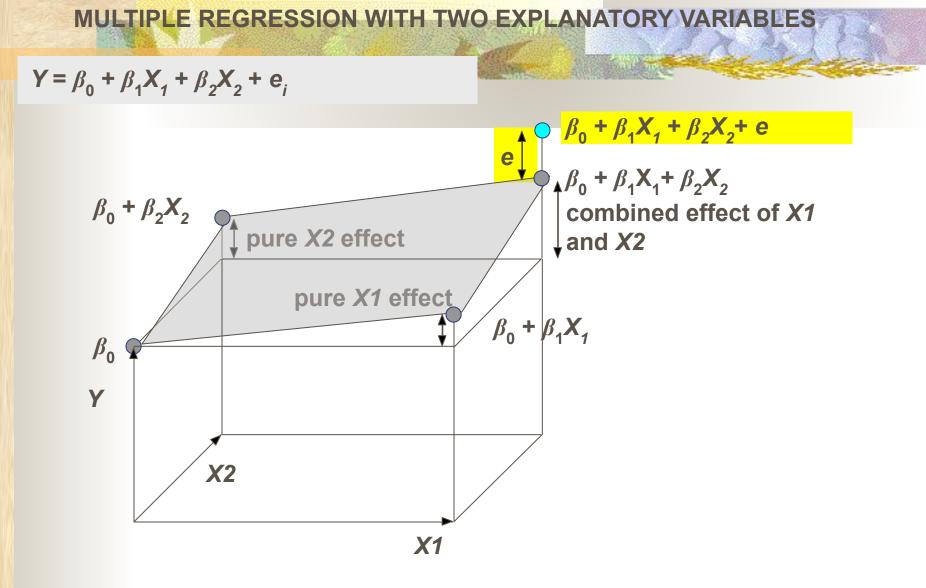

Different combinations of X1 and X2 give rise to values of weekly salary which lie on the plane shown in the diagram, defined by the equation $Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2$. This is the nonrandom component of the model.

The final element of the model is the error term, e. This causes the actual values of Y to deviate from the plane. In this observation, e happens to have a positive value.

A sample consists of a number of observations generated in this way. Note that the interpretation of the model does not depend on whether *X1* and *X2* are correlated or not.

However we do assume that the effects of *X1* and *X2* on *salary* are additive. The impact of a difference in *X1* on *salary* is not affected by the value of *X2*, or vice versa.

$$\hat{Y}_i = b_0 + b_1 X_{1i} + b_2 X_{2i}$$

Slope coefficients are interpreted as partial slope/partial regression coefficients:

MULTIPLE REGRESSION WITH TWO EXPLANATORY VARIABLES

- b₁ = average change in Y associated with a unit change in X₁, with the other independent variables held constant (all else equal);
- D_2 = average change in Y associated with a unit change in X₂, with the other independent variables held constant (all else equal).

$$Y_{i} = \beta_{0} + \beta_{1}X_{1i} + \beta_{2}X_{2i} + e_{i}$$

$$\hat{Y}_i = b_0 + b_1 X_{1i} + b_2 X_{2i}$$

The regression coefficients are derived using the same least squares principle used in simple regression analysis. The fitted value of Y in observation *i* depends on our choice of b_0 , b_1 , and b_2 .

$$Y_{i} = \beta_{0} + \beta_{1}X_{1i} + \beta_{2}X_{2i} + e_{i}$$

$$\hat{Y}_i = b_0 + b_1 X_{1i} + b_2 X_{2i}$$

$$e_i = Y_i - \hat{Y}_i = Y_i - b_0 - b_1 X_{1i} - b_2 X_{2i}$$

The residual e_i in observation *i* is the difference between the actual and fitted values of *Y*.

 $SSE = \sum e_i^2 = \sum (Y_i - b_0 - b_1 X_{1i} - b_2 X_{2i})^2$

We define SSE, the sum of the squares of the residuals, and choose b_0 , b_1 , and b_2 so as to minimize it.

$$SSE = \sum e_i^2 = \sum (Y_i - b_0 - b_1 X_{1i} - b_2 X_{2i})^2$$

 $= \sum (Y_i^2 + b_0^2 + b_1^2 X_{1i}^2 + b_2^2 X_{2i}^2 - 2b_0 Y_i - 2b_1 X_{1i} Y_i$ $- 2b_2 X_{2i} Y_i + 2b_0 b_1 X_{1i} + 2b_0 b_2 X_{1i} + 2b_1 b_2 X_{1i} X_{2i})$ $= \sum Y_i^2 + nb_0^2 + b_1^2 \sum X_{1i}^2 + b_2^2 \sum X_{2i}^2 - 2b_0 \sum Y_i$ $- 2b_1 \sum X_{1i} Y_i - 2b_2 \sum X_{2i} Y_i + 2b_0 b_1 \sum X_{1i}$ $+ 2b_0 b_2 \sum X_{2i} + 2b_1 b_2 \sum X_{1i} X_{2i}$

∂SSE_{-0}	$\frac{\partial SSE}{\partial SSE} = 0$	$\frac{\partial SSE}{\partial SSE} = 0$
$\overline{\partial b_0} = 0$	∂b_1	∂b_2

First we expand SSE as shown, and then we use the first order conditions for minimizing it.

$$b_0 = \overline{Y} - b_1 \overline{X}_1 - b_2 \overline{X}_2$$

$$b_{1} = \frac{\text{Cov}(X_{1}, Y)\text{Var}(X_{2}) - \text{Cov}(X_{2}, Y)\text{Cov}(X_{1}, X_{2})}{\text{Var}(X_{1})\text{Var}(X_{2}) - [\text{Cov}(X_{1}, X_{2})]^{2}}$$

$$b_{2} = \frac{\text{Cov}(X_{2}, Y)\text{Var}(X_{1}) - \text{Cov}(X_{1}, Y)\text{Cov}(X_{1}, X_{2})}{\text{Var}(X_{1})\text{Var}(X_{2}) - [\text{Cov}(X_{1}, X_{2})]^{2}}$$

We thus obtain three equations in three unknowns. Solving for b_0 , b_1 , and b_2 , we obtain the expressions shown above.

$$b_0 = \overline{Y} - b_1 \overline{X}_1 - b_2 \overline{X}_2$$

$$b_{1} = \frac{\text{Cov}(X_{1}, Y)\text{Var}(X_{2}) - \text{Cov}(X_{2}, Y)\text{Cov}(X_{1}, X_{2})}{\text{Var}(X_{1})\text{Var}(X_{2}) - [\text{Cov}(X_{1}, X_{2})]^{2}}$$

$$b_{2} = \frac{\text{Cov}(X_{2}, Y)\text{Var}(X_{1}) - \text{Cov}(X_{1}, Y)\text{Cov}(X_{1}, X_{2})}{\text{Var}(X_{1})\text{Var}(X_{2}) - [\text{Cov}(X_{1}, X_{2})]^{2}}$$

The expression for b_0 is a straightforward extension of the expression for it in simple regression analysis.

$$b_0 = \overline{Y} - b_1 \overline{X}_1 - b_2 \overline{X}_2$$

$$b_{1} = \frac{\text{Cov}(X_{1}, Y)\text{Var}(X_{2}) - \text{Cov}(X_{2}, Y)\text{Cov}(X_{1}, X_{2})}{\text{Var}(X_{1})\text{Var}(X_{2}) - [\text{Cov}(X_{1}, X_{2})]^{2}}$$

$$b_{2} = \frac{\text{Cov}(X_{2}, Y)\text{Var}(X_{1}) - \text{Cov}(X_{1}, Y)\text{Cov}(X_{1}, X_{2})}{\text{Var}(X_{1})\text{Var}(X_{2}) - [\text{Cov}(X_{1}, X_{2})]^{2}}$$

However, the expressions for the slope coefficients are considerably more complex than that for the slope coefficient in simple regression analysis.

$$b_0 = \overline{Y} - b_1 \overline{X}_1 - b_2 \overline{X}_2$$

$$b_{1} = \frac{\text{Cov}(X_{1}, Y)\text{Var}(X_{2}) - \text{Cov}(X_{2}, Y)\text{Cov}(X_{1}, X_{2})}{\text{Var}(X_{1})\text{Var}(X_{2}) - [\text{Cov}(X_{1}, X_{2})]^{2}}$$

$$b_{2} = \frac{\text{Cov}(X_{2}, Y)\text{Var}(X_{1}) - \text{Cov}(X_{1}, Y)\text{Cov}(X_{1}, X_{2})}{\text{Var}(X_{1})\text{Var}(X_{2}) - [\text{Cov}(X_{1}, X_{2})]^{2}}$$

For the general case when there are many explanatory variables, ordinary algebra is inadequate. It is necessary to switch to matrix algebra.

In matrix notation OLS may be written as:

Y = Xb + e

The normal equations in matrix form are now

$$\mathbf{X}^{\mathsf{T}} \mathbf{Y} = \mathbf{X}^{\mathsf{T}} \mathbf{X} \mathbf{b}$$

And when we solve it for b we get:

$$\mathbf{b} = (\mathbf{X}^{\mathsf{T}}\mathbf{X})^{-1}\mathbf{X}^{\mathsf{T}}\mathbf{Y}$$

where Y is a column vector of the Y values and X is a matrix containing a column of ones (to pick up the intercept) followed by a column of the X variables containing the observations on them and *b* is a vector containing the estimators of regression parameters.

$$y = \begin{bmatrix} y_1 \\ y_2 \\ \dots \\ y_n \end{bmatrix} \qquad X = \begin{bmatrix} 1 & X_{11} & X_{21} \\ 1 & X_{12} & X_{22} \\ \dots & \dots & \dots \\ 1 & X_{1n} & X_{2n} \end{bmatrix} \qquad b = \begin{bmatrix} b_0 \\ b_1 \\ b_2 \end{bmatrix}$$

A vector is a collection of n numbers or elements, collected either in a column (a column vector) or in a row (a row vector).

A **matrix** is a collection, or array, of numbers of elements in which the elements are laid out in columns and rows. The dimension of matrix is $n \times m$ where *n* is the number of rows and *m* is the number of columns.

Types of matrices

A matrix is said to be **square** if the number of rows equals the number of columns. A square matrix is said to be **symmetric** if its (i, j) element equals its (j, i) element. A **diagonal** matrix is a square matrix in which all the off-diagonal elements equal zero, that is, if the square matrix A is diagonal, then $a_{ii} = 0$ for $i \neq j$.

The **transpose** of a matrix switches the rows and the columns. That is, the transpose of a matrix turns the $n \times m$ matrix A into the $m \times n$ matrix denoted by A^{T} , where the (i, j) element of A becomes the (j, i) element of A^{T} ; said differently, the transpose of a matrix A turns the rows of A into the columns of A^{T} . The **inverse** of the matrix A is defined as the matrix for which $A^{-1}A=1$. If in fact the inverse matrix A^{-1} exists, then A is said to be **invertible** or **nonsingular**.

Vector and matrix multiplication

The matrices A and B can be multiplied together if they are conformable, that is, if the number of columns of A equals the number of rows of B. In general, matrix multiplication does not commute, that is, in general $AB \neq BA$.

Data for weekly salary based upon the length of employment and age of employees of a large industrial corporation are shown in the table.

	187 11		•
	Weekly	Length of	Age
