INTERPHONE was initiated as an international set of case-control studies focusing on four types of tumours in tissues that most absorb radiofrequency energy emitted by mobile phones: tumours of the brain (glioma and meningioma), parotid gland and acoustic nerve (schwannoma). The objective was to determine whether mobile phone use increases the risk of these tumours and, specifically, whether radiofrequency energy (RF) emitted by mobile phones is tumourigenic.

With the delivery and acceptance of the final report by the funding bodies, the International Agency for Research on Cancer (IARC) announces that the Interphone study was completed in February 2012.

The conduct of the study, the main results, and additional activities aiding in the interpretation of the results are summarized in the [final report](#).
